Extreme Computing

The ACID model versus the BASE methodology

Methodology versus model?

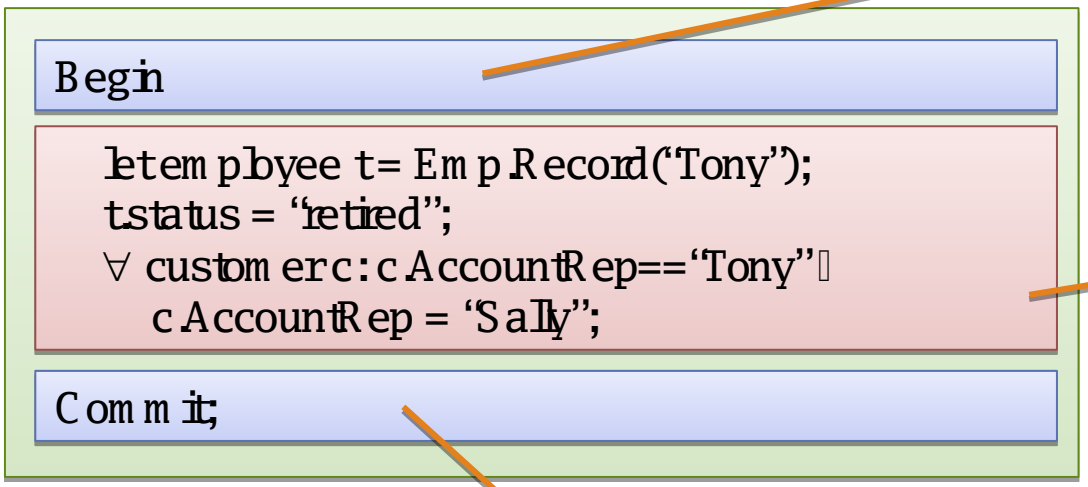
- An apples and oranges debate that has gripped the cloud community
  - A methodology is a way of doing something
    - For example, there is a methodology for starting fires without matches using flint and other materials
  - A model is really a mathematical construction
    - We give a set of definitions (i.e., fault-tolerance)
    - Provide protocols that provably satisfy the definitions
    - Properties of model, hopefully, translate to application-level guarantees

The ACID model

- A model for correct behavior of databases
- Name was coined (no surprise) in California in 60's
  - Atomicity
    - Either it all succeeds, or it all fails
    - Even if transactions have multiple operations, the rest of the world will either see all effects simultaneously (success), or no effects (failure)
  - Consistency
    - A transaction that runs on a correct database leaves it in a correct state
  - Isolation
    - It looks as if each transaction runs all by itself.
    - Transactions are shielded from other transactions running concurrently
  - Durability
    - Once a transaction commits, updates cannot be lost or rolled back
    - Everything is permanent

ACID as a methodology

- We teach it all the time in our database courses
- We use it when developing systems
  - We write transactional code
  - System executes this code in an all-or-nothing way



Begin signals the start of the transaction

Body of the transaction performs reads and writes atomically

Commit asks the database to make the effects permanent. If a crash happens before this, or if the code executes **Abort**, the transaction rolls back and leaves no trace

Why is ACID helpful?

- Developer does not need to worry about a transaction leaving some sort of partial state
  - For example, showing Tony as retired and yet leaving some customer accounts with him as the account rep
- Similarly, a transaction cannot glimpse a partially completed state of some concurrent transaction
  - Eliminates worry about transient database inconsistency that might cause a transaction to crash
  - Analogous situation
    - Thread *A* is updating a linked list and thread *B* tries to scan the list while *A* is running
    - What if *A* breaks a link?
    - *B* is left dangling, or following pointers to nowhere-land

Serial and serialisable execution

- A serial execution is one in which there is at most one transaction running at a time, and it always completes via commit or abort before another starts
- Serialisability is the illusion of serial execution
  - Transactions execute concurrently and their operations interleave at the level of database accesses to primary data
  - Yet a database is designed to guarantee an outcome identical to some serial execution: it masks concurrency
    - This is achieved though some combination of locking and snapshot isolation

All ACID implementations have costs

- Locking mechanisms involve competing for locks
  - Overheads associated with maintaining locks
  - Overheads associated with duration of locks
  - Overheads associated with releasing locks on Commit
- Snapshot isolation mechanisms uses fine-grained locking for updates
  - But also have an additional version based way of handing reads
  - Forces database to keep a history of each data item
  - As a transaction executes, picks the versions of each item on which it will run

These costs are not so small

Dangers of replication

- The costs of transactional ACID model on replicated data in typical settings broadly fall into one of two cases
  - Embarrassingly easy ones
    - Transactions do not conflict at all (like Facebook updates by a single owner to a page that others might read but never change)
  - Conflict-prone ones
    - Transactions that sometimes interfere and in which replicas could be left in conflicting states if care is not taken to order and/or reconcile the updates
- Scalability for the latter case will be terrible
- Recommended solutions involve sharding and coding transactions to favour the first case

Are we doomed?

- The Dangers of Replication and a Solution (Jim Gray, Pat Helland, Dennis Shasha. Proc. 1996 ACM SIGMOD.)
- They do a paper-and-pencil analysis
  - Estimate how much work will be done as transactions execute, roll-back
  - Count costs associated with doing/undoing operations and also delays due to lock conflicts that force waits
- Show that even under very optimistic assumptions slowdown will be $O(n^2)$ in size of replica set (shard)
- If approach is naïve, $O(n^5)$ slowdown is possible!

THE BASE METHODOLOGY

This motivates BASE

- Proposed by eBay researchers
  - Found that many eBay employees came from transactional database backgrounds and were used to the transactional style of thinking
  - But the resulting applications did not scale well and performed poorly on their cloud infrastructure
- Goal was to guide that kind of programmer to a cloud solution that performs much better
  - BASE reflects experience with real cloud applications
  - Opposite of ACID

D. Pritchett. BASE: An Acid Alternative. ACM Queue, July 28, 2008.

Not a model, but a methodology

- BASE involves step-by-step transformation of a transactional application into one that will be far more concurrent and less rigid
  - But it does not guarantee ACID properties
  - Argument parallels (and actually cites) CAP: they believe that ACID is too costly and often, not needed

BASE stands for *Basically Available Soft-State Services with Eventual Consistency*

Terminology

- Basically Available: Like CAP, goal is to promote rapid responses.
  - BASE papers point out that in data centers partitioning faults are very rare and are mapped to crash failures by forcing the isolated machines to reboot
  - But we may need rapid responses even when some replicas can't be contacted on the critical path

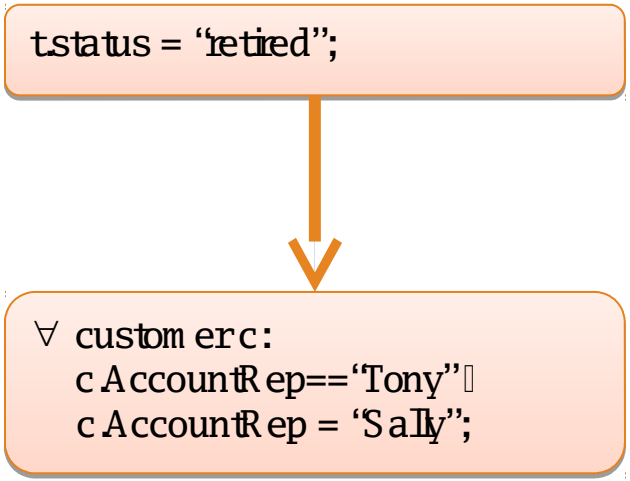
- Soft state service: Runs in first tier
  - Cannot store any permanent data
  - Restarts in a clean state after a crash
  - To remember data either replicate it in memory in enough copies to never lose all in any crash or pass it to some other service that keeps hard state

- Eventual consistency: OK to send optimistic answers to the external client
  - Could use cached data (without checking for staleness)
  - Could guess at what the outcome of an update will be
  - Might skip locks, hoping that no conflicts will happen
  - Later, if needed, correct any inconsistencies in an offline cleanup activity

How BASE is used

- Start with a transaction, but remove Begin/Commit
  - Now fragment it into steps that can be done in parallel, as much as possible
  - Ideally each step can be associated with a single event that triggers that step: usually, delivery of a multicast
- Leader that runs the transaction stores these events in a message queuing middleware system
  - Like an email service for programs
  - Events are delivered by the message queuing system
  - This gives a kind of all-or-nothing behavior

BASE in action

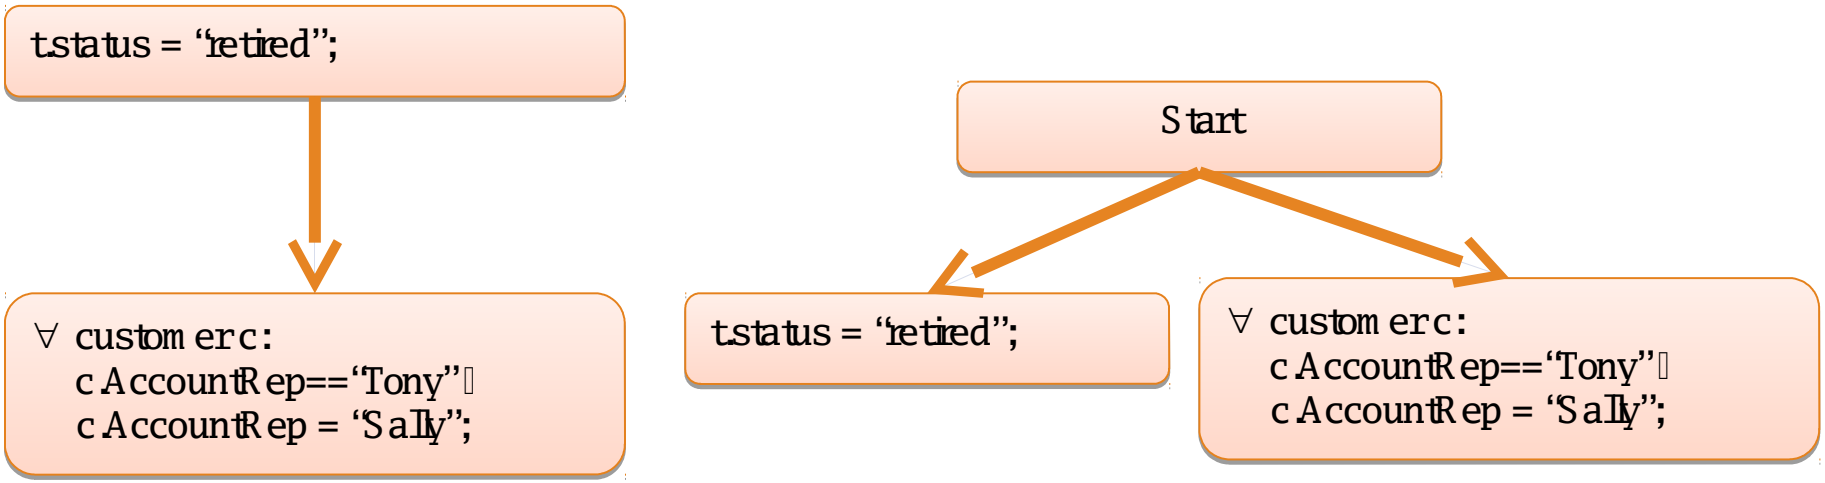


Begin

```
employee t= EmpRecord("Tony");
t.status = "retired";
∀ customer c:c.AccountRep=="Tony"
    c.AccountRep = "Sally";
```

Commit;

BASE in action



- BASE suggestions
  - Consider sending the reply to the user before finishing the operation
  - Modify the end-user application to mask any asynchronous side-effects that might be noticeable
    - In effect, weaken the semantics of the operation and code the application to work properly anyhow
  - Developer ends up thinking hard and working hard!

Before BASE… and after

- Code was often much too slow
  - Poor scalability
  - End-users waited a long time for responses

- With BASE
  - Code itself is way more concurrent, hence faster
  - Elimination of locking, early responses, all make end-user experience snappy and positive
  - But we do sometimes notice oddities when we look hard

BASE side-effects

- Suppose an eBay auction is running fast and furious
  - Does every single bidder necessarily see every bid?
  - And do they see them in the identical order?
- Clearly, everyone needs to see the winning bid
- But slightly different bidding histories should not hurt much, and if this makes eBay 10x faster, the speed may be worth the slight change in behaviour!

- Upload a YouTube video, then search for it
  - You may not see it immediately
- Change the initial frame (they let you pick)
  - Update might not be visible for an hour

- Access a FaceBook page when your friend says she has posted a photo from the party
  - You may see an 
AMAZON DYNAMO

BASE in action: Dynamo

- Amazon was interested in improving the scalability of their shopping cart service

- A core component widely used within their system
  - Functions as a kind of key-value storage solution
  - Previous version was a transactional database and, just as the BASE folks predicted, was not scalable enough
  - Dynamo project created a new version from scratch

Dynamo approach

- Amazon made an initial decision to base Dynamo on a Chord-like Distributed Hash Table (DHT) structure
  - Recall Chord and its O(log n) routing ability
- The plan was to run this DHT in tier 2 of the Amazon cloud system
  - One instance of Dynamo in each Amazon data centre and no linkage between them
- This works because each data centre has ownership for some set of customers and handles all of that person's purchases locally
  - Coarse-grained sharding/partitioning

The challenge

- Amazon quickly had their version of Chord up and running, but then encountered a problem
- Chord was not very tolerant to delays
  - If a component gets slow or overloaded, the hash table was heavily impacted
- Yet delays are common in the cloud (not just due to failures, although failure is one reason for problems)
- So how could Dynamo tolerate delays?

The Dynamo idea

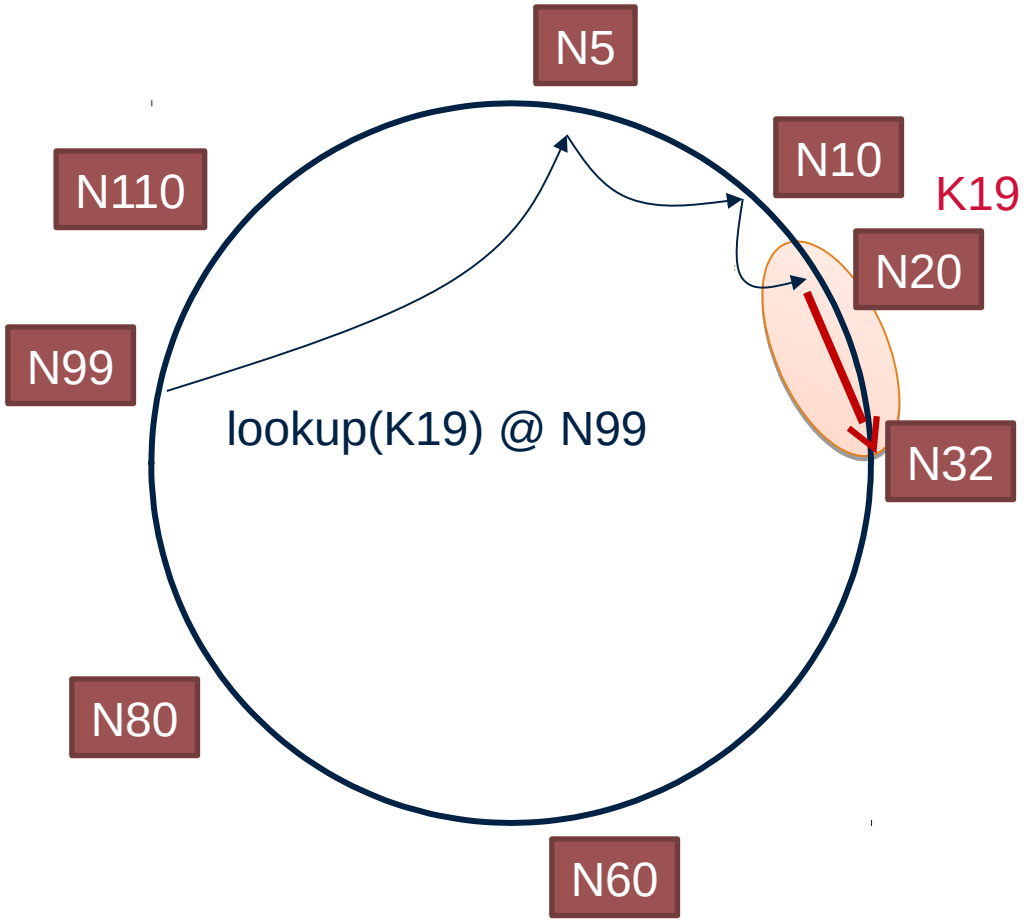
- The key issue is to find the node on which to store a key-value tuple, or one that has the value
- Routing can tolerate delay fairly easily
  - Suppose node *K* wants to use the finger table to route to node $K+2^i$ and gets no acknowledgement
  - Then Dynamo just tries again with node $K+2^{i-1}$
  - This works at the cost of a slight stretch in the routing path, in the rare cases when it occurs

What if the actual owner node fails?

- Suppose that we reach the point at which the next hop should take us to the owner for the hashed key
- But the target does not respond
  - It may have crashed, or have a scheduling problem (overloaded), or be suffering some kind of burst of network loss
  - All common issues in Amazon's data centres
- Then they do the Get/Put on the next node that actually responds even if this is the wrong one
  - Chord will repair

Dynamo example

- Ideally, this strategy works perfectly
  - Chord normally replicates a key-value pair on a few nodes, so we would expect to see several nodes that know the current mapping: a shard
  - After the intended target recovers, the repair code will bring it back up to date by copying key-value tuples
- But sometimes Dynamo jumps beyond the target range and ends up in the wrong shard



Consequences of misrouting (and miss-storing)

- If this happens, Dynamo will eventually repair itself
  - But meanwhile, some slightly confusing things happen
- Put might succeed, yet a Get might fail on the key
- Could cause user to buy the same item twice
  - This is a risk they are willing to take because the event is rare and the problem can usually be corrected before products are shipped in duplicate

Werner Vogels on BASE

- He argues that delays as small as 100ms have a measurable impact on Amazon's income!
  - People wander off before making purchases
  - So snappy response is king
- True, Dynamo has weak consistency and may incur some delay to achieve consistency
  - There isn't any real delay bound
  - But they can hide most of the resulting errors by making sure that applications which use Dynamo don't make unreasonable assumptions about how Dynamo will behave

Summary

- BASE is a widely popular alternative to transactions
  - Basically Available Soft-State Services with Eventual Consistency
- Used (mostly) for first tier cloud applications
- Weakens consistency for faster response, later cleans up
  - Consistency is eventual, not immediate
- eBay, Amazon Dynamo shopping cart both use BASE
